

Beyond Ratings: Measuring the Impact of Guest Experience in Hostel Reviews

Using Review Text to Benchmark Properties, Identify Rating Drivers, and Prioritize Operational Action

Prepared for Mad Monkey Hostels

Prepared by Ian McMurry

Georgia Institute of Technology, Master of Science in Analytics

This report presents a public-review proof of concept for measuring guest experiences using 162,000 reviews, benchmarking Mad Monkey properties against the broader hostel market, and identifying how social experience relates to guest ratings and review activity.

6.4.5	Link guest experience to commercial outcomes	31

Executive Summary

Key Findings

1. **Mad Monkey is substantially more social than the broader hostel market.** Public reviews show that Mad Monkey properties are much more likely to be described as social than the average hostel in the dataset. Across 162,840 reviews from 2,262 hostels in 71 cities, 21.4% of global hostel reviews were classified as social, compared with 53.2% of Mad Monkey reviews.
2. **Every Mad Monkey property is more social than same-city competitors.** When each property is compared only against non-Mad-Monkey hostels in the same city, all 14 Mad Monkey properties show positive and statistically significant social lift. The largest lifts are in Bangkok (+51.9 percentage points), Phuket (+48.0 pp), Chiang Mai (+45.1 pp), and Hanoi (+40.8 pp), while even the lowest-lift properties, East Side and On Broadway, remain above the Sydney competitor baseline by +12.9 pp and +14.0 pp.
3. **The strongest properties are not just social, but high-quality social.** The best-performing properties generate reviews that are social, positive, not dirty, and not negative. Siargao leads on this measure, with 61.3% of reviews classified as high-quality social, followed by Bangkok (52.3%), Siem Reap (50.9%), Phuket (50.0%), and Kings Cross (49.6%).
4. **Some social properties show signs of operational friction.** The analysis separates high-quality social experience from “chaotic social” reviews, where social atmosphere appears alongside dirty or negative signals. Chiang Mai has a strong high-quality social share (45.5%) but also the highest chaotic-social share (15.2%), while Nacpan Beach (13.3%) and Hanoi (12.6%) also show elevated chaotic-social patterns.
5. **Dirty-review signals are property-specific, not brand-wide.** Mad Monkey is consistently differentiated on social atmosphere, but dirty-review signals vary by location. Nacpan Beach has significantly fewer dirty-review signals than same-city competitors (-13.0 pp), while East Side has significantly more (+11.0 pp); most other properties are not statistically distinguishable from their city competitors on dirty-review share.
6. **Social experience is associated with higher review scores.** Reviews classified as social tend to receive higher overall scores, even after accounting for city, review source, cleanliness, dirtiness, calmness, and broad positive sentiment. In the adjusted review-level model, social reviews are associated with a +0.303 point higher score on the 10-point rating scale, clean reviews with +0.245 points, and dirty reviews with a much larger -0.973 point penalty.
7. **Social experience is also associated with higher review activity.** Properties with a higher proportion of social reviews tend to receive reviews more frequently, suggesting that social atmosphere may contribute to guest engagement and review generation. In the review-frequency model, a 10 percentage-point increase in social-share is associated with approximately 8.2% higher monthly review frequency, while a 10 percentage-point increase in dirty-share is associated with approximately 12.5% lower monthly review frequency.

1 Data Overview and Method

1.1 Purpose of the Analysis

This proof-of-concept analysis uses public hostel review text to measure guest-perceived experience across Mad Monkey properties and the broader hostel market. The primary focus is *social atmosphere*: whether guests describe interaction with other travelers, communal participation, organized activities, party/community energy, or the ease of meeting people.

This is different from simply analyzing overall review ratings. A high rating indicates that a guest was satisfied, but it does not explain what kind of experience produced that satisfaction. For Mad Monkey, this distinction matters because the brand is not competing only on generic satisfaction. It is competing on a specific type of hostel experience: social, memorable, and community-oriented stays.

1.2 Dataset Scale and Coverage

The analysis is based on a large public review dataset covering hostels across multiple cities and review platforms. The final working dataset contains 162,840 total reviews, of which 161,378 have valid review dates. The dataset includes 2,262 unique hostels across 71 cities. Within this broader market, the Mad Monkey subset contains 1,571 reviews across 14 properties in 8 cities.

Table 1: Dataset Overview

Metric	Value
Total reviews	162,840
Hostelworld reviews	74,184
Booking.com reviews	88,656
Unique hostels	2,262
Unique cities	71
Mad Monkey reviews	1,571
Mad Monkey properties	14
Mad Monkey cities	8
Median reviews per hostel	65
Mean reviews per hostel	71.99

The dataset is broad enough to support both internal Mad Monkey comparisons and external benchmarking against the wider hostel market. Review coverage is especially strong in major backpacker and tourism markets. The largest cities by review count include Bangkok, Chiang Mai, Barcelona, Tokyo, London, Lisbon, Seoul, Phuket, Sydney, and Prague. The dataset also draws from both major review sources, with 88,656 reviews from Booking.com and 74,184 reviews from Hostelworld.

Figure 1: Top 15 cities by review count in the full hostel review dataset.

1.3 Socialness as a Measurable Experience Dimension

The socialness label used in this analysis is based on a domain-specific transformer pipeline developed for hostel reviews. The model was designed to capture whether a review provides evidence of guest-to-guest interaction, communal atmosphere, organized social activity, or social energy. This is intentionally different from generic sentiment analysis. A review can be positive without being social, and a review can describe a highly social environment even while mentioning negative issues such as noise or cleanliness problems.

The underlying research pipeline trained a cross-encoder on 4,994 manually annotated reviews, applied it to pseudo-label 162,840 additional reviews, and distilled those labels into a sentence-transformer bi-encoder. On held-out human-labeled data, the domain-adapted embeddings achieved an F1 score of 0.826, outperforming generic sentence embeddings with logistic regression (F1 = 0.671) and zero-shot GPT-4o-mini classification (F1 = 0.774). The same work found a 40-fold improvement in intra-class versus inter-class similarity, indicating that the domain-specific embedding space separated social and non-social reviews far more clearly than generic embeddings.

For this reason, the socialness label should not be interpreted as a simple keyword search for words like “party” or “bar.” The model is designed to identify whether the review actually describes social interaction or communal participation. This distinction is important because hostels can have social-looking amenities without guests describing meaningful interaction, and conversely, guests may describe a social atmosphere through implicit situational cues rather than direct phrases such as “this hostel is social.”

1.4 Experience Labels Used in the Analysis

In addition to socialness, the analysis uses five auxiliary review-level labels: calm, clean, dirty, good sentiment, and bad sentiment. These labels allow the analysis to separate social atmosphere from other parts of the guest experience. This is important because a hostel can be social but operationally weak, clean but not social, calm and comfortable, or broadly positive without being socially distinctive.

Table 2: Review-Level Experience Labels

Label	Interpretation
Social	The review describes guest interaction, social atmosphere, communal activity, meeting other travelers, events, or party/community energy.
Calm	The review describes quietness, restfulness, peacefulness, or a calmer stay experience.
Clean	The review positively mentions cleanliness, clean rooms, clean bathrooms, or clean facilities.
Dirty	The review negatively mentions dirtiness, unclean bathrooms, poor cleanliness, or related operational issues.
Good sentiment	The review expresses a broadly positive experience.
Bad sentiment	The review expresses a broadly negative experience or dissatisfaction.

1.5 Label Prevalence in the Global Dataset and Mad Monkey Subset

Across the full global hostel dataset, 21.4% of reviews are classified as social. In the Mad Monkey subset, 53.2% of reviews are classified as social. This large difference is an important initial signal: Mad Monkey reviews are much more likely to describe social atmosphere than the broader hostel market.

The Mad Monkey subset also differs from the global dataset on several other experience dimensions. Mad Monkey has a lower calm-review share than the global hostel average, which is consistent with a more social and energetic brand position. Mad Monkey also has a slightly lower clean-review share and a somewhat higher dirty-review and bad-sentiment share, suggesting that social atmosphere should be evaluated alongside operational quality rather than in isolation.

Table 3: Label Prevalence: Global Dataset vs. Mad Monkey

Label	Global Count	Global Share	Mad Monkey Count	Mad Monkey Share
Social	34,833	21.4%	835	53.2%
Calm	41,930	25.7%	196	12.5%
Clean	49,984	30.7%	385	24.5%
Dirty	22,825	14.0%	267	17.0%
Good sentiment	137,942	84.7%	1,263	80.4%
Bad sentiment	42,146	25.9%	476	30.3%

**Figure 2:** Prevalence of each experience label in the global hostel dataset compared with the Mad Monkey subset.

1.6 Mad Monkey in the Global Socialness Distribution

The global hostel market is heavily skewed toward low socialness. Most hostels have relatively small shares of reviews that explicitly describe social atmosphere. This matches the prior finding from the socialness model that highly social hostels are rare: when review-level predictions are aggregated to the property level, hostel socialness follows an approximate exponential decay pattern, with high-social properties forming a relatively small upper tail.

The histogram below places Mad Monkey properties within this global distribution. Each bar shows the number of hostels at a given level of social-review share, while the vertical markers indicate where individual Mad Monkey properties fall. Most Mad Monkey locations sit well to the right of the global mass of hostels, meaning they are substantially more social than the typical hostel in the broader dataset. This provides a market-level view of Mad Monkey’s social positioning before narrowing the analysis to internal property comparisons and same-city competitor benchmarks.

Figure 3: Global distribution of hostel-level socialness, with Mad Monkey properties marked. Hostels with fewer than 30 reviews are excluded to reduce noise from very small samples.

1.7 Property-Level Aggregation

The analysis begins at the review level and then aggregates to the property level. For each hostel, the social share is calculated as the fraction of that hostel’s reviews classified as social:

$$\text{Social Share}_j = \frac{\text{Number of reviews for property } j \text{ classified as social}}{\text{Total number of reviews for property } j}$$

The same aggregation is used for calm, clean, dirty, good sentiment, and bad sentiment. Each property is therefore represented by an experience profile: the share of reviews associated with each label.

Hostel-level results are grouped using the combination of city and standardized property name:

$$\text{Property Unit} = \text{City} + \text{Standardized Property Name}$$

This avoids treating capitalization differences, spelling variations, or duplicate display names as separate properties. The same property identifier is used consistently across internal Mad Monkey comparisons, same-city competitor benchmarking, rating models, and review-frequency models.

1.8 Analytical Roadmap

The remainder of the report proceeds in four steps.

First, Mad Monkey properties are compared internally to identify which locations have the strongest social, clean, dirty, calm, positive, and negative review profiles.

Second, each Mad Monkey property is benchmarked against same-city competitors. This avoids misleading global comparisons by accounting for the fact that cities differ in baseline hostel culture and review behavior.

Third, review-level regression models estimate how experience labels are associated with overall review scores. These models account for city and review source, making the results more informative than simple average comparisons.

Fourth, property-level count models examine whether experience labels are associated with review frequency. Review frequency is not treated as a direct measure of bookings, but it may indicate review generation, platform activity, guest engagement, or memorability of the stay.

2 Internal Mad Monkey Location Comparisons

2.1 Purpose of the Internal Comparison

Before comparing Mad Monkey properties to external competitors, it is useful to first compare Mad Monkey locations against one another. The goal of this section is not to rank properties by overall quality, but to understand how different locations express the Mad Monkey guest experience.

The central question is:

Which Mad Monkey properties generate social experiences that are also positive, clean, and low in negative guest-experience signals?

To answer this, the analysis combines the review-level experience labels into four diagnostic outcomes. These are designed to distinguish between social atmosphere that appears to be high-quality and social atmosphere that may be accompanied by operational friction.

2.2 Cross-Label Experience Outcomes

The four cross-label outcomes are defined as follows:

Table 4: Cross-Label Experience Outcomes

Outcome	Definition and Interpretation
High-quality social	Reviews classified as social, positive, not dirty, and not negative. This captures social atmosphere that appears to be experienced positively and without major operational complaints.
Chaotic social	Reviews classified as social and also dirty or negative. This captures cases where social atmosphere appears alongside guest dissatisfaction or operational issues.
Clean but not social	Reviews classified as clean and positive, but not social. This captures properties that may be well-run or comfortable, but less explicitly social in guest reviews.
Calm positive but not social	Reviews classified as calm and positive, but not social. This captures properties that may provide a pleasant, quieter experience, but may be less aligned with a high-energy social positioning.

These categories are not intended to be a complete decomposition of all review types. Instead, they are diagnostic indicators that help separate different kinds of guest experience. In particular, “high-quality social” and “chaotic social” are useful because they distinguish social atmosphere that appears to be clearly positive from social atmosphere that appears alongside negative or dirty-review signals.

2.3 High-Quality Social Experience by Property

Figure 4 shows the share of reviews at each Mad Monkey property that are classified as high-quality social. This is one of the most useful internal metrics because it does not treat all social reviews equally. A high-quality social review is one where the guest describes social atmosphere while also expressing positive sentiment and avoiding dirty or negative-experience signals.

Figure 4: Share of reviews classified as high-quality social by Mad Monkey property.

The strongest properties on this measure are Mad Monkey Siargao, Mad Monkey Bangkok, Mad Monkey Siem Reap, Mad Monkey Phuket, and Mad Monkey Kings Cross. These properties each have approximately half or more of their reviews classified as high-quality social. Mad Monkey Siargao is the clear leader, with 61.3% of reviews falling into the high-quality social category.

At the lower end, Mad Monkey East Side, Mad Monkey On Broadway, Mad Monkey Coogee Beach, and Mad Monkey Downtown have lower high-quality social shares. This does not necessarily mean these are poor properties. Rather, it means that fewer reviews at these locations describe the specific combination of social atmosphere, positive sentiment, and low operational complaint signals.

Table 5: Mad Monkey Cross-Label Experience Outcomes

Property	High-Quality Social	Chaotic Social	Clean Not Social	Calm Not Social
Mad Monkey Siargao	61.3%	9.0%	1.8%	2.7%
Mad Monkey Bangkok	52.3%	9.3%	0.9%	1.9%
Mad Monkey Siem Reap	50.9%	9.4%	12.3%	4.7%
Mad Monkey Phuket	50.0%	8.2%	7.3%	5.5%
Mad Monkey Kings Cross	49.6%	8.4%	5.0%	5.9%
Mad Monkey Chiang Mai	45.5%	15.2%	7.1%	6.3%
Mad Monkey Bayswater	43.5%	5.3%	10.7%	9.2%
Mad Monkey Potts Point	43.0%	9.4%	5.5%	1.6%
Mad Monkey Hanoi	40.5%	12.6%	12.6%	4.5%
Mad Monkey Nacpan Beach	38.3%	13.3%	5.8%	10.0%
Mad Monkey Downtown	37.1%	7.1%	10.0%	4.3%
Mad Monkey Coogee Beach	33.9%	11.0%	6.4%	6.4%
Mad Monkey On Broadway	32.2%	7.6%	14.4%	7.6%
Mad Monkey East Side	30.3%	8.4%	7.6%	5.9%

2.4 High-Quality Social Versus Chaotic Social

Figure 5 compares each property on two dimensions: high-quality social share and chaotic social share. The ideal position is toward the lower-right of the chart: high high-quality social share and low chaotic social share.

Figure 5: High-quality social share versus chaotic social share by Mad Monkey property.

This chart suggests several useful internal distinctions.

Mad Monkey Siargao appears to be the strongest internal benchmark. It has the highest high-quality social share and only a moderate chaotic social share. Mad Monkey Bangkok, Siem Reap, Phuket, and Kings Cross also appear in a strong region of the chart, combining relatively high high-quality social shares with comparatively manageable chaotic-social levels.

Mad Monkey Chiang Mai is more nuanced. It has a strong high-quality social share, but it also has the highest chaotic-social share among the Mad Monkey properties. This does not mean that the property is underperforming overall. Rather, it suggests that its social atmosphere may be more intense or more operationally demanding. This property may be producing meaningful social experiences, but with a higher risk of negative or complaint-linked reviews.

Mad Monkey Bayswater is also notable. It has a mid-to-high high-quality social share and the lowest chaotic-social share. This may indicate a more controlled or balanced guest experience. By contrast, Mad Monkey Nacpan Beach and Mad Monkey Hanoi have lower high-quality social shares and relatively high chaotic-social shares, suggesting possible opportunities to improve the quality or consistency of the social experience.

The main takeaway is that internal social performance should not be evaluated by socialness alone. A property can be social in a way that is positive and brand-enhancing, or social in a way that is more mixed with operational friction.

2.5 Cross-Label Experience Composition

Figure 6 shows the relative prevalence of the four diagnostic cross-label outcomes by property. This visualization provides a broader view of how each Mad Monkey location is perceived in review text.

Figure 6: Cross-label experience composition by Mad Monkey property. Categories are diagnostic and may not represent a complete mutually exclusive partition of all reviews.

The composition chart reinforces the distinction between properties that are primarily social and properties that may have stronger clean or calm non-social signals. Siargao, Bangkok, Siem Reap, Phuket, and Kings Cross show the strongest high-quality social blocks. These properties appear most aligned with Mad Monkey’s core social positioning.

Some properties show larger clean-but-not-social or calm-positive-but-not-social shares. For example, Mad Monkey On Broadway, Hanoi, Siem Reap, Bayswater, and Downtown show relatively visible clean-but-not-social components. Mad Monkey Nacpan Beach and Bayswater show relatively visible calm-positive-but-not-social components. These patterns are not necessarily negative. They may indicate that guests are noticing comfort, cleanliness, or calmness. However, from a brand-positioning perspective, they may also indicate that some positive experiences are not being described as explicitly social.

This distinction matters operationally. A clean, calm, positive stay can still be a good stay, but it may not fully express the Mad Monkey social brand. Conversely, a property with high social atmosphere but elevated chaotic-social share may need stronger operational controls to preserve the value of that social energy.

2.6 Internal Management Interpretation

The internal comparison suggests four broad property patterns.

Social experience leaders. Mad Monkey Siargao, Bangkok, Siem Reap, Phuket, and Kings Cross appear to be the strongest internal examples of high-quality social experience. These properties are useful benchmarks for understanding what successful social atmosphere looks like in public review text.

Social but higher-friction properties. Mad Monkey Chiang Mai, Nacpan Beach, and Hanoi show relatively elevated chaotic-social shares. These properties may still be socially strong, but the social experience appears more likely to coexist with negative or operational complaint signals.

Balanced or comfort-oriented properties. Mad Monkey Bayswater stands out for combining a reasonable high-quality social share with the lowest chaotic-social share. Properties with larger clean-but-not-social or calm-positive-but-not-social components may be delivering positive stays that are less explicitly social.

Social activation opportunities. Mad Monkey East Side, On Broadway, Coogee Beach, and Downtown have lower high-quality social shares relative to other Mad Monkey locations. These properties may warrant closer review to determine whether the issue is social programming, guest mix, physical layout, operational quality, or simply local market positioning.

Overall, the internal results suggest that Mad Monkey’s properties should not be managed against a single socialness score. The more useful distinction is between *high-quality social atmosphere* and *social atmosphere with operational friction*. The strongest properties are those where guests describe social energy in positive terms and without accompanying dirty or negative-experience signals.

3 External Benchmarking Against Same-City Competitors

3.1 Purpose of External Benchmarking

Internal comparisons show how Mad Monkey properties differ from one another. However, internal comparisons alone do not answer whether Mad Monkey is differentiated relative to the broader hostel market. To evaluate this, each Mad Monkey property is compared against non-Mad-Monkey hostels in the same city.

This same-city comparison is important because hostel culture differs substantially by market. A hostel in Bangkok should not be evaluated against a hostel in Sydney or Siargao without accounting for city context. Some cities are naturally more social, while others may have a calmer or more general accommodation mix. The same-city benchmark therefore asks a more useful question:

Is this Mad Monkey property more social than other hostels in its own local market?

For each label, the city-adjusted lift is calculated as:

$$\text{City-Adjusted Lift}_j = \text{Label Share}_j - \text{Average Label Share of Same-City Competitors}$$

For example, a social lift of 0.30 means that the property has a social-review share 30 percentage points higher than the average non-Mad-Monkey hostel in the same city.

3.2 Social Lift Versus Same-City Competitors

Figure 7 shows the social-review lift for each Mad Monkey property relative to same-city competitors. Every Mad Monkey property has a positive social lift, meaning every location has a higher social-review share than the average non-Mad-Monkey hostel in its city.

Figure 7: Mad Monkey social-review share minus same-city competitor average. Blue bars indicate differences that are statistically significant after false-discovery-rate adjustment.

The strongest city-adjusted social lift appears in Bangkok, Phuket, Chiang Mai, and Hanoi. Mad Monkey Bangkok has a social-review share of 61.7%, compared with a same-city competitor average of 9.8%, producing a social lift of 51.9 percentage points. Mad Monkey Phuket has a social-review share of 58.2%, compared with a same-city competitor average of 10.2%, producing a social lift of 48.0 percentage points. Mad Monkey Chiang Mai and Mad Monkey Hanoi also show very large lifts of 45.1 and 40.8 percentage points, respectively.

Importantly, the lower end of the Mad Monkey social-lift distribution is still positive. Even Mad Monkey East Side and Mad Monkey On Broadway, which were among the lower internal performers, still exceed the Sydney competitor baseline. Mad Monkey East Side has a social-review share of 38.7%, compared with a Sydney competitor average of 25.8%, producing a positive lift of 12.9 percentage points. Mad Monkey On Broadway has a social-review share of 39.8%, producing a positive lift of 14.0 percentage points.

Table 6: Mad Monkey Social Lift Versus Same-City Competitors

Property	Social Share	City Avg.	Lift	FDR Sig.
Mad Monkey Bangkok	61.7%	9.8%	+51.9 pp	Yes
Mad Monkey Phuket	58.2%	10.2%	+48.0 pp	Yes
Mad Monkey Chiang Mai	61.6%	16.5%	+45.1 pp	Yes
Mad Monkey Hanoi	53.2%	12.4%	+40.8 pp	Yes
Mad Monkey Kings Cross	58.0%	25.8%	+32.2 pp	Yes
Mad Monkey Siargao	70.3%	40.2%	+30.1 pp	Yes
Mad Monkey Nacpan Beach	51.7%	22.6%	+29.1 pp	Yes
Mad Monkey Siem Reap	60.4%	31.3%	+29.0 pp	Yes
Mad Monkey Potts Point	52.3%	25.8%	+26.5 pp	Yes
Mad Monkey Bayswater	48.9%	25.8%	+23.1 pp	Yes
Mad Monkey Coogee Beach	45.0%	25.8%	+19.2 pp	Yes
Mad Monkey Downtown	44.3%	25.8%	+18.5 pp	Yes
Mad Monkey On Broadway	39.8%	25.8%	+14.0 pp	Yes
Mad Monkey East Side	38.7%	25.8%	+12.9 pp	Yes

A two-proportion test was used to evaluate whether each Mad Monkey property’s social-review share differs from the same-city competitor baseline. All fourteen Mad Monkey properties have statistically significant positive social lift after false-discovery-rate adjustment. This is one of the clearest findings in the analysis: Mad Monkey properties are not merely social in absolute terms; they are consistently more social than other hostels in their own cities.

3.3 Dirty-Review Lift Versus Same-City Competitors

The dirty-review benchmark provides a complementary operational view. For social atmosphere, a positive lift is desirable. For dirty-review share, the interpretation is reversed: a negative lift is favorable because it means the property has fewer dirty-review signals than same-city competitors.

Figure 8 shows dirty-review lift for each Mad Monkey property.

Figure 8: Mad Monkey dirty-review share minus same-city competitor average. Blue bars indicate differences that are statistically significant after false-discovery-rate adjustment. Negative values indicate fewer dirty-review signals than same-city competitors.

The dirty-review results are more mixed than the social results. Most Mad Monkey properties are not statistically distinguishable from same-city competitors on dirty-review share. This is important: while Mad Monkey is consistently and significantly more social than competitors, it is not consistently cleaner or dirtier across all markets.

Two properties are statistically significant after FDR adjustment. Mad Monkey Nacpan Beach has a dirty-review share of 7.5%, compared with an El Nido competitor average of 20.5%, producing a favorable dirty lift of -13.0 percentage points. This suggests that Nacpan Beach receives substantially fewer dirty-review signals than same-city competitors.

Mad Monkey East Side moves in the opposite direction. It has a dirty-review share of 32.8%, compared with a Sydney competitor average of 21.7%, producing an unfavorable dirty lift of +11.0 percentage points. This difference is statistically significant after FDR adjustment and suggests that dirty-review signals are a specific area of concern for this property.

Table 7: Mad Monkey Dirty-Review Lift Versus Same-City Competitors

Property	Dirty Share	City Avg.	Lift	FDR Sig.
Mad Monkey East Side	32.8%	21.7%	+11.0 pp	Yes
Mad Monkey Coogee Beach	26.6%	21.7%	+4.9 pp	No
Mad Monkey On Broadway	25.4%	21.7%	+3.7 pp	No
Mad Monkey Chiang Mai	11.6%	10.4%	+1.2 pp	No
Mad Monkey Phuket	14.5%	14.3%	+0.3 pp	No
Mad Monkey Downtown	21.4%	21.7%	-0.3 pp	No
Mad Monkey Potts Point	21.1%	21.7%	-0.7 pp	No
Mad Monkey Bangkok	10.3%	11.6%	-1.3 pp	No
Mad Monkey Siem Reap	5.7%	8.8%	-3.1 pp	No
Mad Monkey Siargao	13.5%	17.3%	-3.8 pp	No
Mad Monkey Kings Cross	17.6%	21.7%	-4.1 pp	No
Mad Monkey Bayswater	17.6%	21.7%	-4.2 pp	No
Mad Monkey Hanoi	11.7%	17.1%	-5.4 pp	No
Mad Monkey Nacpan Beach	7.5%	20.5%	-13.0 pp	Yes

3.4 Interpretation

The external benchmarking section produces a clear strategic finding:

Mad Monkey properties are consistently and significantly more social than same-city competitors, but operational complaint signals vary by property.

This matters because it separates brand differentiation from operational execution. On social atmosphere, the Mad Monkey brand is strongly visible in public review text. Every property exceeds its local competitor baseline, and every social-lift result is statistically significant after adjustment for multiple comparisons.

The dirty-review results show a more property-specific pattern. Most locations are approximately in line with local competitors, some appear better than competitors, and one location, Mad Monkey East Side, shows a statistically significant dirty-review disadvantage. This suggests that the main brand-level strength is social atmosphere, while cleanliness and dirty-review signals require more targeted property-level management.

3.5 Management Implications

The most important management implication is that Mad Monkey’s social positioning appears externally validated. The brand is not merely claiming to be social; guests describe Mad Monkey properties as social at rates substantially above same-city competitors.

However, social differentiation should not be treated as a substitute for operational quality. The dirty-review benchmark suggests that some properties deliver social atmosphere without elevated dirty-review signals, while others may allow operational issues to dilute the guest experience. Mad Monkey Nacpan Beach is a positive example on this dimension, with significantly fewer dirty-review signals than same-city competitors. Mad Monkey East Side is the clearest operational flag, with significantly higher dirty-review share than its Sydney competitor baseline.

Overall, the external benchmark supports two parallel conclusions:

1. Mad Monkey has a clear and statistically supported social-atmosphere advantage relative to local competitors.
2. The value of that social advantage depends on maintaining operational quality, especially around cleanliness and negative guest-experience signals.

4 Effect of Guest Experiences on Overall Hostel Ratings

4.1 Purpose of the Rating Model

The previous sections showed that Mad Monkey properties are more social than same-city competitors and that some properties produce a higher-quality social experience than others. The next question is whether these experience labels are associated with the overall review scores guests leave.

This section asks:

When a review describes social atmosphere, cleanliness, calmness, or dirtiness, how is that associated with the guest’s overall rating?

This is important because a simple average comparison can be misleading. Reviews come from different cities and platforms, and those contexts may have different rating patterns. For example, Hostelworld users may rate differently than Booking.com users, and hostels in one city may generally receive higher or lower scores than hostels in another city.

To reduce this problem, the model includes controls for city and review source. In plain language, this means the model compares reviews while accounting for baseline differences between cities and platforms.

4.2 Model Specification

The main rating model estimates the association between review-level experience labels and the guest’s overall score. The outcome is the review’s overall rating on a 10-point scale.

The main adjusted model is:

$$\text{Overall Score}_i = \beta_0 + \beta_1 \text{Social}_i + \beta_2 \text{Calm}_i + \beta_3 \text{Clean}_i + \beta_4 \text{Dirty}_i + \beta_5 \text{Good Sentiment}_i + \gamma_{\text{City}} + \delta_{\text{Source}} + \epsilon_i$$

where each experience label is binary at the review level. For example, $\text{Social}_i = 1$ if review i is classified as social and 0 otherwise.

The city controls account for differences across local markets. The source control accounts for differences between review platforms. The model also uses clustered standard errors, which makes the uncertainty estimates more conservative when reviews from the same property may be related to one another.

A coefficient can be interpreted as the estimated difference in overall review score associated with that label, holding the other included factors constant. For example, a social coefficient of +0.30 means that social reviews tend to score about 0.30 points higher on the 10-point rating scale, after accounting for city, source, cleanliness, dirtiness, calmness, and general positive sentiment.

4.3 Main Rating Results

The adjusted model explains a substantial portion of the variation in overall review scores, with an R^2 of 0.554. This is much higher than the simpler model without good sentiment, which had an R^2 of 0.288. This increase is expected because broad positive sentiment is naturally very closely related to overall ratings.

However, the key result is that socialness remains positive and statistically significant even after accounting for good sentiment. This suggests that social atmosphere is not merely a proxy for a generally positive review. It appears to contribute additional information about the guest experience.

Table 8: Adjusted Associations with Overall Review Score

Review Label	Coefficient	95% Confidence Interval	Interpretation
Social	+0.303	[0.283, 0.322]	Higher score
Clean	+0.245	[0.230, 0.260]	Higher score
Calm	+0.103	[0.087, 0.118]	Slightly higher score
Dirty	-0.973	[-1.005, -0.941]	Lower score
Good sentiment	+3.357	[3.310, 3.405]	Much higher score

Figure 9: Associations between experience labels and overall review score after accounting for city, review source, and good sentiment.

The model results support several practical conclusions.

First, social atmosphere has a positive relationship with ratings. Reviews classified as social are associated with approximately a +0.30 point increase in overall score, even after accounting for general positive sentiment. This is important because it suggests that socialness is not just another way of saying the review was positive. It is a specific experience dimension with its own relationship to ratings.

Second, cleanliness also has a positive relationship with ratings. Reviews classified as clean are associated with approximately a +0.25 point increase in overall score, holding the other factors constant.

Third, dirty-review signals have a much larger negative relationship with ratings. Reviews classified as dirty are associated with approximately a -0.97 point decrease in overall score, even after accounting for good sentiment and other labels. This is one of the most operationally important results in the report. Social atmosphere helps, but dirty-review signals can impose a much larger penalty.

Fourth, calmness has a smaller positive association with ratings. Calm reviews are associated with approximately a +0.10 point increase. This suggests that calmness can be positive, but its relationship with ratings is weaker than socialness, cleanliness, or dirtiness.

4.4 Why This Is Stronger Than a Simple Correlation

A simple correlation or average comparison would only show whether social reviews tend to have higher scores. That would be useful, but incomplete.

The regression model is more informative because it asks a more controlled question:

Among reviews from similar city and platform contexts, and after accounting for other experience labels, how is each guest-experience dimension associated with the overall score?

This matters because social reviews might also be more positive in general, or might come disproportionately from certain cities or platforms. By including city, source, and good sentiment in the model, the analysis reduces the risk of mistaking those background differences for the effect of social atmosphere.

This does not prove causality. The model does not prove that making a hostel more social will automatically increase ratings by exactly 0.30 points. Instead, it shows that, in observed review data, socialness is consistently associated with higher review scores even after accounting for several important alternative explanations.

4.5 Interaction Model: Do Experiences Combine Differently?

The next model examines whether experience labels combine additively or whether certain combinations behave differently. This is useful because guest experience is rarely one-dimensional. A review might be social and clean, social and calm, or clean and calm.

The interaction model includes terms such as:

$$\text{Social}_i \times \text{Clean}_i$$

This checks whether reviews that are both social and clean receive an additional boost beyond simply adding the social effect and the clean effect separately.

Figure 10: Main and interaction effects in the review-score model.

The interaction model produces a few important findings.

The main social coefficient remains positive. In the interaction model, the social label is associated with approximately +0.36 points when the relevant interacting labels are not present. Cleanliness is also positive, while dirtiness remains strongly negative.

The social-clean interaction is negative, approximately -0.14 . This does *not* mean that clean social reviews are bad. Instead, it means that the combined effect of socialness and cleanliness is less than perfectly additive.

For example, using the interaction model:

$$\text{Social only effect} \approx +0.365$$

$$\text{Clean only effect} \approx +0.293$$

$$\text{Social} + \text{clean effect} \approx 0.365 + 0.293 - 0.139 = +0.519$$

So a review that is both social and clean is still associated with a higher score. The negative

interaction simply means that the combined benefit is smaller than adding the full social bonus and full clean bonus separately. This is a diminishing-returns pattern, not a conflict between social atmosphere and cleanliness.

The clean-calm interaction is also negative, though smaller. This again suggests that positive experience signals can overlap. Once a review is already clean or calm, the additional marginal boost from another positive label may be smaller.

The social-calm interaction is not statistically significant in this model. This suggests that the data does not provide strong evidence that socialness and calmness combine in a distinct way after accounting for the other model terms.

4.6 Management Interpretation

The main operational interpretation is:

Social atmosphere is associated with higher review scores, but it is not a substitute for operational quality.

This is one of the most important findings for Mad Monkey. The model suggests that socialness contributes positively to guest ratings, even after accounting for general positivity. However, dirty-review signals have a much larger negative association with ratings than the positive lift associated with socialness or cleanliness.

In practical terms, this means Mad Monkey should not think of social atmosphere and operational basics as separate priorities. The highest-value guest experience is likely produced when social energy is delivered alongside clean, reliable, low-friction operations.

The results support three conclusions:

1. **Social atmosphere has measurable rating value.** Reviews that describe social atmosphere tend to receive higher scores, even after accounting for broad positive sentiment.
2. **Cleanliness also matters, but dirty-review signals matter even more.** Clean reviews are associated with higher scores, while dirty reviews are associated with a much larger score penalty.
3. **Positive experience features show diminishing returns.** Socialness and cleanliness are both beneficial, but their effects are not perfectly additive. The practical takeaway is not that these features conflict, but that one positive feature cannot simply stack unlimited rating gains on top of another.

Overall, the rating models reinforce the broader story of the report: Mad Monkey's social atmosphere is a real and valuable experience dimension, but its full value depends on protecting the operational foundations of the stay.

5 Effect of Guest Experience on Review Frequency

5.1 Purpose of the Review-Frequency Analysis

The previous section examined how guest-experience labels relate to overall review scores. This section asks a different question:

Are certain guest-experience profiles associated with more review activity?

Review frequency is not the same as bookings or occupancy. A property may receive more reviews because it has more guests, because guests are more motivated to leave reviews, because the experience is more memorable, because the property is more visible on booking platforms, or because of platform-specific review behavior. Therefore, review frequency should not be interpreted as a direct measure of demand.

However, review frequency is still commercially useful. It can be interpreted as a public signal of review generation, guest engagement, platform activity, and the extent to which guests are motivated to document their experience. If social atmosphere is associated with more review activity, that suggests social experience may matter not only for satisfaction, but also for how actively guests talk about the property online.

5.2 How Review Frequency Was Measured

For each hostel, review frequency was calculated using dated reviews. The analysis counted the number of dated reviews for each property and divided that count by the length of the observed review window.

$$\text{Reviews per 30 Days}_j = \frac{\text{Number of dated reviews for property } j}{\text{Active review months for property } j}$$

where active review months is calculated from the time between the first and last dated review for the property. This prevents properties with longer review histories from automatically appearing more active simply because they have been observed for more time.

5.3 Mad Monkey Review Frequency Compared with Same-City Competitors

Table 9 summarizes Mad Monkey review frequency relative to same-city competitor averages. Several properties show substantially higher review activity than their local market baselines. Mad Monkey Phuket, Bangkok, and Chiang Mai have the highest review-frequency ratios, each receiving approximately 3.7 to 4.2 times the same-city competitor review-frequency baseline.

Table 9: Mad Monkey Review Frequency Versus Same-City Competitors

Property	Reviews / 30 Days	City Avg.	Ratio vs. City	Social Lift
Mad Monkey Phuket	26.79	7.68	4.24x	+48.0 pp
Mad Monkey Bangkok	25.85	8.62	3.95x	+51.8 pp
Mad Monkey Chiang Mai	24.53	8.31	3.75x	+45.1 pp
Mad Monkey Siargao	16.32	6.76	2.76x	+30.1 pp
Mad Monkey Hanoi	26.40	16.57	2.43x	+40.5 pp
Mad Monkey Potts Point	16.03	10.37	2.22x	+25.6 pp
Mad Monkey Siem Reap	16.13	15.44	1.57x	+29.0 pp
Mad Monkey Kings Cross	10.35	10.37	1.43x	+31.2 pp
Mad Monkey Coogee Beach	9.43	10.37	1.31x	+18.2 pp
Mad Monkey Nacpan Beach	9.49	11.50	1.15x	+29.1 pp
Mad Monkey On Broadway	8.31	10.37	1.15x	+13.0 pp
Mad Monkey East Side	6.80	10.37	0.94x	+11.9 pp
Mad Monkey Downtown	5.68	10.37	0.79x	+17.5 pp
Mad Monkey Bayswater	5.07	10.37	0.70x	+22.1 pp

The table shows that social lift and review frequency are related but not identical. For example, Mad Monkey Siargao has the highest social share, but Phuket, Bangkok, Chiang Mai, and Hanoi show the highest review-frequency levels. This suggests that review activity is influenced by more than socialness alone. It may also reflect property size, platform visibility, seasonality, market volume, operational history, or review collection behavior.

5.4 Modeling Review Frequency

To estimate how guest-experience labels relate to review frequency across the broader hostel dataset, I used a Negative Binomial count model. This model is appropriate because the outcome is a count: the number of dated reviews for each hostel.

A simple count model would be misleading because hostels have different review-window lengths. A property observed for 24 months naturally has more opportunity to collect reviews than a property observed for 6 months. To handle this, the model includes an exposure offset for active review months. In plain language, this means the model estimates review activity per month rather than raw review volume.

The model is:

$$\text{Review Count}_j \sim \text{Negative Binomial}$$

$$\log(\text{Expected Monthly Review Rate}_j) = \beta_0 + \beta_1 \text{Social Share}_j + \beta_2 \text{Clean Share}_j + \beta_3 \text{Dirty Share}_j + \beta_4 \text{Calm Share}_j + \gamma$$

The city controls account for baseline differences in review activity across markets. This matters because some cities naturally generate more review activity than others.

The Negative Binomial model was used instead of a simple Poisson model because review counts are highly uneven across properties. Some hostels receive far more reviews than others, and the Negative Binomial model is designed to handle this extra variation.

5.5 Main Review-Frequency Results

Figure 11 shows the estimated percent change in monthly review frequency associated with a 10 percentage-point increase in each property-level label share.

Figure 11: Estimated change in monthly review frequency associated with a 10 percentage-point increase in each label share.

Table 10: Negative Binomial Model: Estimated Review-Frequency Effects

Property-Level Label	Coefficient	Effect of +10 pp	Interpretation
Social share	+0.791	+8.2%	Higher review frequency
Clean share	+0.505	+5.2%	Higher review frequency
Dirty share	-1.339	-12.5%	Lower review frequency
Calm share	-2.112	-19.0%	Lower review frequency

The results suggest that properties with higher social-review share tend to receive reviews more frequently. A 10 percentage-point increase in social share is associated with approximately 8.2% higher monthly review frequency, holding city, clean share, dirty share, and calm share constant.

Clean share is also positively associated with review frequency. A 10 percentage-point increase in clean share is associated with approximately 5.2% higher monthly review frequency.

Dirty share and calm share move in the opposite direction. A 10 percentage-point increase in dirty share is associated with approximately 12.5% lower monthly review frequency. A 10 percentage-point increase in calm share is associated with approximately 19.0% lower monthly review frequency.

5.6 Interpretation

The review-frequency model supports a commercially relevant interpretation:

Social atmosphere is associated not only with higher review scores, but also with greater review activity.

This does not prove that social atmosphere causes higher occupancy or more bookings. The analysis does not include internal booking, occupancy, revenue, or guest-count data. However, the result does suggest that social atmosphere is linked to review generation and public guest engagement.

The positive clean-share result is also important. It suggests that operational quality may support review activity. Properties that are clean and social may be more likely to generate frequent public reviews than properties that are social but operationally inconsistent.

The negative dirty-share result suggests that dirty-review signals are associated with weaker review activity. This may seem counterintuitive because negative experiences can sometimes motivate complaints. However, at the property level, dirty-review share may also signal lower-quality properties, weaker demand, worse platform visibility, or lower guest engagement.

The negative calm-share result should be interpreted carefully. Calmness is not necessarily bad. Some guests want a quiet or peaceful stay. However, within the hostel market, calmer properties may be less likely to generate frequent public reviews, possibly because the experience is less socially memorable, less event-driven, or less aligned with the backpacker social segment.

5.7 Management Implications

The review-frequency results extend the rating analysis in an important way. The rating model showed that social reviews are associated with higher overall scores. The review-frequency model suggests that properties with higher social-review share may also generate more reviews per month.

For Mad Monkey, this supports the idea that social atmosphere has value beyond guest satisfaction alone. It may also contribute to public review activity, digital visibility, and the volume of guest-generated content.

The operational implication is not simply to maximize socialness at all costs. The strongest pattern across the report is that social atmosphere is most valuable when paired with clean, positive, low-friction execution. Dirty-review signals are associated with lower ratings and lower review frequency, while clean-review signals are associated with both higher ratings and higher review frequency.

In practical terms, Mad Monkey should treat social atmosphere as a measurable brand asset, but one that depends on operational quality. Social energy may help drive engagement, but cleanliness and guest-experience reliability protect the value of that engagement.

6 Conclusion, Limitations, and Areas for Expansion

6.1 Conclusion

This proof of concept shows that Mad Monkey's social atmosphere is visible in public review text, measurable at scale, and meaningfully differentiated from the broader hostel market. Across the

global hostel dataset, 21.4% of reviews are classified as social. Within the Mad Monkey subset, that figure rises to 53.2%, indicating that guests describe Mad Monkey properties as social at more than twice the rate of the broader market.

The same pattern remains when properties are benchmarked against same-city competitors. Every Mad Monkey property has a positive social lift relative to other hostels in its local market, and every social-lift result is statistically significant after adjustment for multiple comparisons. This is one of the clearest findings in the report: Mad Monkey's social positioning is not only present in brand identity, it is reflected in guest language.

This statistically proves and quantifies the effect that socialness has on hostel ratings. These ratings are typically the first thing backpackers see when deciding on a hostel to book; these ratings can make or break a hostel. The results showed that reviews that describe social atmosphere are associated with higher overall scores, even after accounting for city, review source, and broad positive sentiment. Cleanliness is also positively associated with review scores, while dirty-review signals are strongly negative.

The review-frequency model extends the same story: properties with higher social-review share tend to receive more reviews per month, while dirty and calm review shares are associated with lower review frequency. Whether the review frequency reflects occupancy or simply the propensity a guest is to write a review remains unknown. Regardless, it has been proven that socialness is critical for the prosperity of a hostel.

Taken together, the findings support a practical strategic conclusion:

Mad Monkey's social atmosphere is a measurable brand asset. Socialness of a hostel is statistically linked to higher scores and review frequency even when stratifying for generic positive experiences. In other words socialness allows a hostel to break out from above average to world-reknowned, and Mad Monkey by and large does a good job of fostering this.

6.2 Managerial Implications

The analysis creates a framework for managing guest experience beyond overall ratings. Rather than asking only whether a property is rated highly, Mad Monkey can ask what type of experience guests are describing.

This creates several practical uses.

Identify social experience leaders. Properties such as Siargao, Bangkok, Siem Reap, Phuket, and Kings Cross appear to be strong examples of high-quality social experience. These locations can be studied as internal benchmarks for social programming, staff behavior, common-space activation, events, and guest mix.

Separate social strength from operational friction. Some properties may be strongly social but also show elevated chaotic-social or dirty-review signals. These locations may not need less social energy. They may need stronger operational controls around cleanliness, quiet hours, staffing, facilities, or guest-flow management.

Find social activation opportunities. Properties with lower high-quality social share may still be delivering positive stays, but not necessarily the distinct Mad Monkey social experience. These properties may benefit from targeted event programming, community-building initiatives, better common-space use, or closer investigation into guest demographics and property layout.

Use review text as an operating signal. Public reviews can function as a low-cost listening system. With regular updates, the same approach could monitor whether social atmosphere, cleanliness, dirty-review signals, and negative sentiment are improving or deteriorating by property.

Move from brand claim to measurable KPI. Social atmosphere is often treated as intangible. This analysis shows that it can be turned into a measurable property-level signal. That creates the foundation for tracking social atmosphere over time, comparing properties, evaluating initiatives, and connecting guest experience to business outcomes.

6.3 Limitations

The results should be interpreted as a public-review proof of concept rather than a complete operational diagnosis. The analysis uses external review data, so it cannot directly observe occupancy, revenue, staffing decisions, event calendars, guest demographics, or property-specific operating context.

The models show associations, not guaranteed causal effects. For example, social atmosphere is associated with higher review scores and higher review frequency, but the analysis does not prove that increasing socialness alone would automatically raise ratings or review volume. Other factors, such as property size, location, seasonality, platform visibility, and guest mix, may also contribute.

The review-frequency results should also be interpreted carefully. Review frequency is not the same as bookings or demand. It is better understood as a public signal of review generation, guest engagement, and platform activity.

These limitations do not weaken the value of the proof of concept. Rather, they define the next step: combining public-review intelligence with internal operating data.

6.4 Areas for Expansion

The strongest next step is to turn this public-review analysis into an applied operating tool for Mad Monkey. Several extensions would make the analysis more actionable.

6.4.1 Add internal operating data

The most important expansion would be to incorporate internal Mad Monkey data, such as occupancy, revenue, room type, events calendars, staffing patterns, bar activity, guest demographics, and property-level operating notes. This would allow the analysis to move beyond external benchmarking and begin answering operational questions such as:

- How much extra are guests willing to pay for a social hostel?
- What is relationship between socialness of a hostel and its occupancy?
- Which events are associated with increases in high-quality social reviews?

- Which properties convert social programming into higher ratings or review activity?
- Where do dirty or negative-review signals suppress the value of social atmosphere?
- Are changes in staffing, management, or facilities visible in review text over time?

6.4.2 Create a recurring property-level dashboard

The current proof of concept could be converted into a recurring dashboard that tracks each property on a small set of interpretable metrics:

- Social-review share
- High-quality social share
- Chaotic-social share
- Dirty-review share
- Bad-sentiment share
- Review frequency
- Same-city social lift
- Same-city dirty-review lift

This would give leadership a consistent way to monitor whether each property is strengthening or weakening on the experience dimensions most relevant to the brand.

6.4.3 Develop property-specific playbooks

Once strong and weak patterns are identified, the analysis could support property-specific recommendations. For example, a property with low social share but strong clean-positive reviews may need social activation. A property with high social share but high chaotic-social share may need operational controls. A property with high dirty-review lift may need targeted facilities or housekeeping review.

This turns the model from an analytics exercise into a management tool.

6.4.4 Monitor changes over time

The current report focuses mostly on cross-sectional comparisons. A future version could track monthly or quarterly changes in social atmosphere and guest-experience signals. This would allow Mad Monkey to evaluate whether interventions are working.

Examples include:

- Before-and-after analysis around new events programming
- Seasonal monitoring of social atmosphere
- Property relaunch or renovation impact analysis
- Early warning signals for rising dirty or negative-review patterns

6.4.5 Link guest experience to commercial outcomes

The most valuable expansion would connect review-derived guest-experience metrics to internal business outcomes. With occupancy, revenue, average daily rate, booking lead time, and channel data, Mad Monkey could test whether social atmosphere predicts commercial performance.

This would allow the analysis to move from:

Social atmosphere is associated with review scores and review frequency.

to a more operationally powerful question:

Which forms of social atmosphere are associated with stronger property performance?
